

Amdahl's Law

Exercise 1

Assume 1% of the runtime of a program is not parallelizable. This program is run on 61 cores of a Intel Xeon Phi. Under the assumption that the program runs at the same speed on all of those cores, and there are no additional overheads, what is the parallel speedup?

Solution

Amdahl's law assumes that a program consists of a serial part and a parallelizable part. The fraction of the program which is serial can be denoted as B — so the parallel fraction becomes $1 - B$. If there is no additional overhead due to parallelization, the speedup can therefore be expressed as

$$S(n) = \frac{1}{B + \frac{1}{n}(1 - B)}$$

For the given value of $B = 0.01$ we get $S(61) = 38.125$.

Exercise 2

Assume that the program invokes a broadcast operation. This broadcast adds overhead, depending on the number of cores involved. There are two broadcast implementations available. One adds a parallel overhead of $0.0001 \times n$, the other one $0.0005 \times \log(n)$. For which number of cores do you get the highest speedup for both implementations?

Solution

$$S_1(n) = \frac{1}{0.001 + \frac{1}{n}0.999 + 0.0001n}$$

$$S_2(n) = \frac{1}{0.001 + \frac{1}{n}0.999 + 0.0005 \log(n)}$$

We can get the maximum of these terms if we minimize the term in denominator.

$$\frac{\partial}{\partial n}0.001 + \frac{1}{n}0.999 + 0.0001n = 0 \leftrightarrow 0.0001 - \frac{0.999}{n^2} = 0 \rightarrow n \approx 100$$

$$\frac{\partial}{\partial n}0.001 + \frac{1}{n}0.999 + 0.0005 \log(n) = 0 \leftrightarrow \frac{0.005n - 0.999}{n^2} = 0 \rightarrow n = 1998$$

Exercise 3

By Amdahl's law, it does not make much sense to run a program on millions of cores, if there is only a small fraction of sequential code (which is often inevitable, i.e., reading input data). Why do people build such systems anyway?

Solution

Amdahl's law Assumes that the problem size is kept constant — by adding more processors the same problem gets solved faster. In HPC it is often the case that bigger computers are used to solve bigger problems, not to solve old problems faster.

If the sequential part of the program does not increase when increasing the input (or increases sublinearly) then we can run on a large number of cores.

PRAM Model

Exercise 1

We can find the minimum from an unordered collection of n natural numbers by performing a reduction along a binary tree: In each round, each processor compares two elements, and the smaller element gets to the next round, the bigger one is discarded. What is the work and depth of this algorithm?

The dependency graph of this computation has $\log_2(n)$ levels, which is equal to the depth/span and contains $\frac{n}{2^l}$ nodes at level l . Therefore The work (number of nodes) in this graph is therefore $2n - 1$.

Exercise 2

Develop an Algorithm which can find the minimum in an unordered collection of n natural numbers in $O(1)$ time on a PRAM machine.

Assume the input list is stored in the array `input`. We use n^2 processors, labelled $p_{(i,j)}$ with $0 \leq i, j < n$. Each processor $p_{(i,j)}$ performs the comparison `input[i] < input[j]`. If the result is false and $i \neq j$ then i can not be the smallest element, and `tmp[i]` is set to false (all elements are initially set to true). Then n processors check the different values of `tmp` - only one element `tmp[x]` will be true, that means `input[x]` is the smallest element.
